### Abstract

Analyses of sediment cores from Jellybean Lake, a small, evaporation-insensitive groundwater-fed lake, provide a record of changes in North Pacific atmospheric circulation for the last ~7500 yr at 5- to 30-yr resolution. Isotope hydrology data from the southern Yukon indicate that the oxygen isotope composition of water from Jellybean Lake reflects the composition of mean-annual precipitation,  $\delta^{18}\text{O}_p$ . Recent changes in the  $\delta^{18}\text{O}$  of Jellybean sedimentary calcite ( $\delta^{18}\text{O}_{ca}$ ) correspond to changes in the North Pacific Index (NPI), a measure of the intensity and position of the Aleutian Low (AL) pressure system. This suggests that  $\delta^{18}\text{O}_p$  variability was related to the degree of fractionation during moisture transport from the Gulf of Alaska across the St. Elias Mountains and that Holocene shifts were controlled by the intensity and position of the AL. Following this model, between ~7500 and 4500 cal yr B.P., long-term trends suggest a predominantly weaker and/or westward AL. Between ~4500 and 3000 cal yr B.P. the AL shifted eastward or intensified before shifting westward or weakening between ~3000 and 2000 cal yr B.P. Rapid shifts eastward and/or intensification occurred ~1200 and 300 cal yr B.P. Holocene changes in North Pacific atmospheric circulation inferred from Jellybean Lake oxygen isotopes correspond with late Holocene glacial advances in the St. Elias Mountains, changes in North Pacific salmon abundance, and shifts in atmospheric circulation over the Beaufort Sea. © 2005 University of Washington. ### Introduction

The intensity and position of the Aleutian Low (AL), the semi-permanent low pressure located over the Gulf of Alaska, has emerged as an important control on Northwest Pacific Holocene climate (e.g., Edwards et al., 2001; Heusser et al., 1985; Latif and Barnett, 1994; Mann et al.,

1998). Decadal scale variability of the AL have been recognized from analyses of instrumental data and is described by climate indices such as the North Pacific index (NPI) (Trenberth and Hurrell, 1994) and the Pacific Decadal Oscillation (PDO) (Mantua et al., 1997). These indices are correlated with tree-ring and salmon abundance data (e.g., Biondi et al., 2001; Mantua et al., 1997) and snow accumulation, a proxy for moisture delivery (Bitz and Battisti, 1999; Moore et al., 2002a,b; Rupper et al., 2004). The AL is the main synoptic climate feature related to moisture delivery to the St. Elias Mountains of Alaska and the interior of the southern Yukon (Mock et al., 1998; Wahl et al., 1987). The St. Elias Mountains have a dramatic effect on the oxygen-isotope values of precipitation on both the coastal and interior sides of the mountains. Relatively  $^{18}\text{O}$ -

enriched precipitation falls on the coastal side compared to strongly  $^{18}\text{O}$ -depleted precipitation just 200 km inland. This large fractionation between coastal and interior precipitation suggests that changes in air mass trajectories and moisture transport history from the Gulf of Alaska either over or around the St. Elias Mountains are a principle influence on precipitation- $\delta^{18}\text{O}$  at Jellybean Lake, located ~250 km inland in the southwest interior Yukon (Fig. 1).

Few studies have documented long-term high-resolution climatic variability beyond the last millennia from high latitudes in northwestern North America (e.g., Anderson et al., 2001; Heusser et al., 1985; Hu et al., 2001; Pienitz et al., 2000). Although recent climatic and environmental changes around the Gulf of Alaska have been documented by tree-ring and ice core studies (D'Arrigo et al., 1999; Davi et al., 2003; Holdsworth et al., 1992; Mann et al., 1998; Wake et al., 2002; Wiles et al., 1998, 1999), these records generally extend from <100 to a maximum of ~1000 cal yr B.P. Comparatively little is known about high-resolution climatic variability during the Holocene in the nearby interior

regions of the Yukon Territory (Pienitz et al., 2000). Holocene climate changes at century to millennial time scales in the interior Yukon Territory were inferred by geomorphological evidence of late Holocene glacial advances (Calkin et al., 2001; Denton and Karlen, 1977), pollen records (Cwynar, 1988; Cwynar and Spear, 1995; Heusser et al., 1985; Keenan and Cwynar, 1992; Lacourse and Gajewski, 2000; Spear and Cwynar, 1997; Wang and Geurts, 1991), and multi-proxy paleolimnological investigations (Pienitz et al., 2000).

There is considerable spatial climatological variability in the southern Yukon Territory and adjacent Alaska due to complex topography and the influence of air masses originating in the Arctic, Gulf of Alaska, and Bering Sea (Streten, 1974; Wahl et al., 1987). Such regional climatic heterogeneity and absence of long-term high-resolution paleoclimatic data make it difficult to adequately describe sub-century scale regional paleoclimate and investigate forcing mechanisms that caused Holocene climatic change. Recent studies have explored the possibility of cyclic

Figure 1. (a) Location map showing the Yukon Territory and sites referred to in the text. variations in solar output (Hu et al., 2003; Wiles et al., 2004) and North Pacific ocean-atmosphere circulation changes (Heusser et al., 1985; Moore et al., 2002a,b; Spooner et al., 2003).

We analyzed oxygen isotopes in sediment cores from Jellybean Lake (Fig. 1), located in the southern Yukon interior, to improve the detail and resolution of the regional climatic history and investigate mechanisms for Holocene climatic change. Jellybean Lake is a small, hydrologically open lake located in the rain shadow of the St. Elias Mountains. Precipitation of calcium carbonate occurs within the water column, thereby allowing us to measure sedimentary carbonate oxygen isotope ratios to produce a record of paleoenvironmental change. The sampling resolution, sensitivity of the geochemical data, and chronology are of sufficient detail at this new site to document Holocene climatic variability at ~5- to 30-yr resolution back to ~7500 cal yr B.P.

### Paleoclimatic application of Jellybean Lake oxygen isotopes

Oxygen isotope ratios of authigenic lake sediment carbonate ( $\delta^{18}\text{O}_{\text{Ca}}$ ) are related to climate because  $\delta^{18}\text{O}_{\text{Ca}}$  is a function of (1) lake water temperature and (2) lake water  $\delta^{18}\text{O}$ . The latter is, in turn, controlled by lake hydrology and regional climate (e.g., Edwards et al., 1996; Talbot, 1990; von Grafenstein et al., 1996). Lake water  $\delta^{18}\text{O}$  in hydrologically closed lakes with a small catchment to surface area ratio may be strongly influenced by the effects of evaporation. Increased evaporation leads to lake water  $^{18}\text{O}$ -enrichment. In contrast, hydrologically open lakes that have large catchment to surface area ratio, or short residence times, are typically less affected by evaporation. In such lakes the  $\delta^{18}\text{O}$  is mainly controlled by the  $\delta^{18}\text{O}$  of inflow water. The oxygen isotope composition of inflow water is influenced by several processes within the climate system including the source of the moisture, its transport path and rainout history, as well as seasonality and the air temperature during precipitation events (Ingraham, 1998). There is a strong correlation between air temperature and the  $\delta^{18}\text{O}$  of precipitation in northern latitudes (Dansgaard, 1964; Rozanski et al., 1992). Derivations of past atmospheric temperature from lacustrine-sediment  $\delta^{18}\text{O}$  usually assume that other factors such as changes in moisture source area, transport, and air mass history are relatively insignificant (e.g., Hu and Shemesh, 2003; Shemesh et al., 2001), which will not always be the case. One way to assess these factors is through studying modern isotopic, hydrologic, and limnologic conditions of the individual lakes within a study area (e.g., Hammerlund et al., 2003; Leng and Anderson, 2003; Rosqvist et al., 2004). Comparing modern lake water  $\delta^{18}\text{O}$  with environmental factors such as hydrology and elevation allows more reliable climatic interpretations of paleo-lake water  $\delta^{18}\text{O}$  results.

### Field area

Jellybean Lake (informal name, 60.35°N, 134.80°W, 730 m a.s.l.) is a small (0.4 km<sup>2</sup>), relatively deep (11.6 m), elongate lake located 40 km south of Whitehorse in the southern Yukon Territory, Canada (Fig. 1). The lake is situated in a large esker complex characterized by numerous narrow ridges 15- to 50-m high composed of well-sorted gravel and sand. The esker complex presumably formed in sub-glacial and englacial tunnels during deglaciation of the southern Yukon ~11,000 yr ago (Dyke et al., 2002). The 50-m high esker ridges along the north, east, and west sides of the lake define the lake basin. The watershed is dominated by open stands of trembling aspen (*Populus tremuloides*) and white spruce (*Picea glauca*). Sage (*artemesia*) and grasses (*poaceae*) grow on the well-drained south facing slopes. The surrounding esker ridges define a small local watershed around the lake and there is no surface inflow or outflow. A broad north-south trending ridge, 1640 m a.s.l., defining the eastern side of the Robinson Valley, is located ~12 km east of Jellybean Lake and likely provides the source area for the local groundwater.

Jellybean Lake is located ~250 km northeast of the Gulf of Alaska (Fig. 1). Coastal climate stations report over 3000 mm/yr of annual precipitation, but a strong rain shadow effect limits annual precipitation in the southern interior regions to ~250 mm/yr (Wahl et al., 1987). Approximately 60% of annual precipitation occurs during ice-free months between May and September, when daylight is at a maximum (Fig. 2). The Gulf of Alaska is the primary source region for airflow in the Yukon (Wahl et al., 1987). Mean annual temperatures at Whitehorse are between -2° and 0°C. July mean temperatures are between 10° and 15°C (Environment Canada, 2003; Fig. 2). Monthly  $\delta^{18}\text{O}$  measurements between 1962 and 1964 A.D. show a seasonal  $\delta^{18}\text{O}$  cycle ranging from -24.6‰ to -16.8‰ (IAEA/WMO, 2001; Fig. 2). More  $^{18}\text{O}$ -enriched precipitation occurs during the summer months. The average  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  from May through September between 1961 and 1965 A.D. was -18.3‰ and -142.8‰, respectively (Table 1). Mean annual  $\delta^{18}\text{O}$  and  $\delta^2\text{H}$  values were -20.4‰ and -160.1‰ from 1962 to 1964 A.D.

### Methods

Water samples were collected from Jellybean Lake, seven nearby lakes, three local springs, and 61 other lakes throughout the southern Yukon in July 2000 and 2002 to document the local and regional isotope hydrology (Anderson, 2005). Samples were taken from near-shore areas or the middle of each lake in a 30-ml HDLP Nalgene bottle. Bottles were rinsed with lake water before sample collection and sealed to avoid air bubbles. Precipitation was collected from a sustained rain event on August 6, 2000 (Table 1). Water samples were analyzed for oxygen and hydrogen

Figure 2. Monthly mean temperature (black line) and total precipitation (gray bars) at Whitehorse, Yukon Territory, between 1944 and 1990 A.D. (Environment Canada, 2003) shown with monthly averages of oxygen isotope ratios of precipitation between 1962 and 1964 A.D. (filled circle; IAEA/WMO, 2001).

isotopic composition by automated constant temperature equilibration with  $\text{CO}_2$  and automated H/D preparation systems, respectively, for isotope ratio mass spectrometry. Results are expressed as  $\delta$  values, representing deviations in per mil (‰) from standard mean ocean water (VSMOW) such that  $\delta_{\text{sample}} = [(R_{\text{sample}} / R_{\text{standard}}) - 1] \times 1000\text{‰}$ , where  $R$  is the  $^{18}\text{O}/^{16}\text{O}$  and  $^2\text{H}/^1\text{H}$  ratios in sample and standard, respectively. Analytical uncertainties are within  $\pm 0.5\text{‰}$  and  $\pm 0.05\text{‰}$  for hydrogen and oxygen, respectively.

Water column temperature, pH, conductivity, and dissolved oxygen were measured in July of 2000 with a Hydrolab Surveyor 4 and Datasonde 4 device. Dissolved carbon dioxide in surface lake water ( $p\text{CO}_2$ ) was determined by applying Henry's Law to samples of ambient air and samples of  $\text{CO}_2$  gas collected from a head space of known volume from a container of agitated lake water (Plummer and Busenberg, 1982). Surface water samples for cation and anion chemistry were collected in 30 ml HDLP Nalgene bottles and stored in the dark at cool temperatures. Alkalinity was determined by titration in the laboratory. Cation and anion concentrations were determined by a Dionex DX500 ion chromatograph and reported in  $\text{mgL}^{-1}$  (Table 2).

Lake bathymetry was determined by sonar soundings (Fig. 1). A 78-cm and 3.6-m long sediment core were retrieved from the deepest parts of Jellybean Lake from a floating platform in July 2000 and 2002 using a modified Livingstone square rod coring device that allowed preser-

vation and extrusion of the uppermost sediments in 0.5 cm increments. Multiple sedimentary properties were used to describe the general sedimentology of the cores. Sediments were visually logged to identify Munsell color, sedimentary structures, and biogenic features. Magnetic suscepti-

bility was used as a proxy for changes in mineral content and measured on half cores at a 0.5-cm interval with a Bartington susceptibility meter (Thompson, 1986). Wet and dry bulk density and water content were determined. Weight percent organic matter and calcium carbonate were determined by the loss-on-ignition (%LOI) method (Bengtsson and Enell, 1986; Heiri et al., 2001). Weight percent CaCO<sub>3</sub> was estimated based on the proportion of CO<sub>2</sub> in CaCO<sub>3</sub> using the following calculation: [%LOI – 1000°C × (100 / 44)].

The sediment core chronology is based on <sup>210</sup>Pb, <sup>137</sup>Cs, AMS <sup>14</sup>C measurements on identifiable macrofossils, and the White River tephra (Clague et al., 1995; Table 3). Terrestrial macrofossils were not present in sufficient quantities for radiocarbon measurements at some stratigraphic levels. Therefore, purified spruce pollen samples were used (Brown et al., 1989). Both measured and calibrated ages are reported, but only calibrated ages are used for discussion. Radiocarbon ages were calibrated using CALIB 4.1 following Stuiver et al. (1998). <sup>210</sup>Pb and <sup>137</sup>Cs activities for Jellybean Lake were measured on 0.5-cm slices extruded in the field from a polycarbonate-barrel piston interface core. A constant rate of supply model (CRS) was used to determine <sup>210</sup>Pb ages (Appleby, 2001; Fig. 3). A prominent <sup>137</sup>Cs peak is within 0.5 cm of the slice estimated to correspond to 1963 A.D. based on the <sup>210</sup>Pb age model, leading to an estimate of ±5-yr precision for the last 100 yr. An age model for Jellybean Lake was constructed using the <sup>210</sup>Pb and <sup>137</sup>Cs data, 7 <sup>14</sup>C measurements, and the White River tephra (Fig. 4f). A linear interpolation between dated depths was used to determine ages of sediment samples. The chronology indicates a fairly uniform sedimentation rate, ~0.05 to 0.075 mm/yr. Based on sedimentation rates and sample thickness, the oxygen and carbon isotope samples integrate 3–6 yr in the uppermost 16.5 cm and 10–30 yr for the remainder of the core.

The core was continuously sampled at high resolution for oxygen and carbon isotopes. Sub-samples of bulk sediment were taken at a 0.5-cm increment for the uppermost 30 field-

extruded samples and every 1 cm for the remainder of the core for a total of 351 samples. The samples were freeze dried, examined for purity, and powdered before subsampling and CO<sub>2</sub> extraction by a Kiel automated device for isotope ratio mass spectrometry on a Finnigan Delta XL mass ratio spectrometer. Oxygen and carbon isotope results are expressed as δ values, representing deviations in per mil (‰) from the Vienna Pee Dee Belemnite standard (VPDB) such that  $\delta_{\text{sample}} = [(R_{\text{sample}} / R_{\text{standard}}) - 1] \times 1000\text{‰}$ , where  $R$  is the <sup>18</sup>O/<sup>16</sup>O and <sup>13</sup>C/<sup>12</sup>C ratios in sample and standard, respectively. Analytical uncertainties are within ±0.1‰ and ±0.05‰ for oxygen and carbon, respectively. δ<sup>18</sup>O<sub>Ca</sub> and δ<sup>13</sup>C<sub>Ca</sub> values were duplicated within the range of analytical error.

## Results

### *Limnology and isotope hydrology of Jellybean Lake*

Jellybean Lake is currently thermally unstratified and chemically mixed. The water column measurements indicate only minor changes in temperature, pH, specific conductivity, and dissolved oxygen with water depth (Anderson, 2005). Sub-surface artesian springs feed the lake at several depths, presumably maintaining the mixed state during the ice-free season. Water level appears to vary inter-annually, as the lake level in July 2002 was 1 m higher than July 2000. Inter-annual lake level variability is probably related to seasonal and annual changes in hydraulic pressure in the recharge area. Jellybean Lake water has a pH of 8.2 and is supersaturated in CO<sub>2</sub>, rich in dissolved calcium and cooler (14.8°C) than a nearby thermally stratified, hydrologically closed lake of similar size (16.3°C; Table 2). Jellybean Lake specific conductivity and major ion concentrations are lower than the hydrologically closed lake, reflecting the effects of short residence times. The δ<sup>18</sup>O of Jellybean Lake water (average –20.4‰) was identical to mean annual precipitation (–20.4‰) and almost identical to local spring water

sampled within a few km of Jellybean Lake (−21.5‰; Table 2). Since groundwater dynamics tend to smooth the effects of individual rainstorms and seasonal variations, groundwater-δ<sup>18</sup>O tends to reflect mean annual isotope composition of precipitation (Gonfiantini et al., 1998; Ingraham, 1998; Tables 1 and 2).

We conducted a survey of the oxygen and hydrogen isotope ratios of water throughout the southern Yukon to compare Jellybean Lake water with precipitation, springs, rivers, and other lakes in the region (Fig. 5; Table 2). Hydrologically closed lakes in this region are strongly influenced by evaporation as indicated by relatively δ<sup>18</sup>O-enriched isotope values. The precipitation data from

Whitehorse and Mayo were used to define the local meteoric water line (LMWL) and has a slope of ~6. The LMWL has a slightly lower slope than the global meteoric water line (GMWL) which has a slope of ~8. Surface water from lakes in the Yukon defines a local evaporation line (LEL) with a slope of ~4. The LEL has a lower slope than the LMWL and GMWL because diffusion controlled isotopic fractionation that occurs during evaporation causes greater <sup>18</sup>O-<sup>16</sup>O separations than <sup>2</sup>H-<sup>1</sup>H. Most evaporation-sensitive lakes have δ<sup>18</sup>O values ranging between −14‰ and −7.7‰. In contrast, most evaporation-insensitive lakes such as Jellybean Lake have more depleted δ<sup>18</sup>O values ranging between −22‰ and −17‰. The intersection point

of the LEL and LMWL defines the average isotope values for unmodified mean annual precipitation and corresponds with our data for groundwater and Jellybean Lake.

Taken together, the strong similarities between Jellybean Lake  $\delta^{18}\text{O}$  and regional groundwater, precipitation, and other hydrologically open lakes suggest that despite its small catchment and lack of surface inflow or outflow, Jellybean Lake acts as an evaporation-insensitive lake. Sub-surface inflow and outflow must be rapid enough to prevent significant evaporative enrichment above the regional average of precipitation and groundwater  $\delta^{18}\text{O}$  values. Jellybean Lake water  $\delta^{18}\text{O}$  is therefore a good representative of regional precipitation. Surface sediment carbonate in Jellybean Lake is in isotopic equilibrium with lake water  $\delta^{18}\text{O}$  as indicated by the temperature equation of Epstein et al. (1953). The predicted surface water value for  $\delta^{18}\text{O}_{\text{Ca}}$  at

14.8°C of  $-20.3\text{‰}$  (VPDB) is very similar to the measured  $\delta^{18}\text{O}_{\text{Ca}}$  value of  $-19.9\text{‰}$  (VPDB; Table 3).

#### Core sedimentology

A suite of multi-proxy sedimentary analyses was performed on cores from Jellybean Lake to document changes in paleolimnology and evaluate controls on the isotope data. The 340-cm sediment stratigraphy is primarily composed of olive to light gray laminated marl with minor mineral matter, reflected by low magnetic susceptibility and dry bulk density (Fig. 4). The White River tephra at 64 cm (1150 cal yr B.P.; Clague et al., 1995) is easily identified both visually and by a sharp increase in magnetic susceptibility ( $\sim 60$  SI). The calcium carbonate content varies between 80% and 85%. Sedimentary laminations are

typically between 0.25- and 1.0-cm thickness. Smear slide analyses indicate that the color variations between laminae are caused by changes in the relative proportion of organic carbon and calcium carbonate content. The lake water is clear (Secchi disk depths >8 m) and calcite crystals form within the water column when photosynthetic activity alters the bicarbonate equilibrium during intense periods of productivity. Smear slide studies of the sediments show that they are nearly pure authigenic micrite. Other carbonate components such as ostracode tests, charophyte encrustations, mollusks, and gastropod shells were not observed in the nearly pure fine-grained calcium carbonate muds with the exception of some gastropods in the lowermost 15 cm.

Sedimentary color, texture, and composition variations are generally consistent throughout the core. The only exception is where ~30 cm of sediment overlying the White River tephra at 64 cm depth are darker and more faintly laminated. Calcium carbonate weight percentages decrease to less than 5% and organic carbon increases by ~30%. Magnetic susceptibility values are slightly higher, reflecting a higher proportion of mineral material that was also evident in smear slide observations. Nevertheless, by ~34 cm-depth, calcium carbonate concentrations recover to >30% and range from ~40% to 60% to the core top. The uniform character of the sediments throughout the majority of the core suggests that physical and chemical characteristics similar to the modern lake have been stable for the last ~7500 yr.

In addition to the evidence for inter-annual water level variations observed at Jellybean Lake today, there is sedimentary evidence for lake level changes in the past. There are two visible changes in the sediments to pelletized marl between 150–160 cm and 240–250 cm (Fig. 4). Such pelletized marls were noted on sub-aerial shoreline surfaces around the lake today. There are minor changes in the bulk density within these intervals, but organic carbon and calcium carbonate content are not significantly altered. If these layers were formed during lower lake levels, with possible sub-aerial exposure, neither the oxygen isotope values nor the sediment accumulation rates appear to have been affected (Fig. 6). The events were either sufficiently brief and/or the open-hydrological status of the lake remained unaffected because these periods were not registered in the  $\delta^{18}\text{O}_{\text{Ca}}$  record.

#### *Oxygen and carbon isotopes*

Oxygen isotope values of sedimentary carbonate vary between  $-18.5\text{‰}$  and  $-20.5\text{‰}$  (Figs. 2 and 6; Table 1). Carbon isotopes have a larger range of variability ( $\sim 4.5\text{‰}$ ) and are relatively  $^{13}\text{C}$ -depleted ( $-3.5\text{‰}$  to  $-7.5\text{‰}$ ). The oxygen and carbon isotopes are poorly correlated ( $r = 0.24$ ), a general characteristic of carbonates formed in open lake systems (Talbot, 1990). However, both the  $\delta^{18}\text{O}_{\text{Ca}}$  and  $\delta^{13}\text{C}_{\text{Ca}}$  rapidly decrease near the White River tephra at 64

cm. Close examination of the data indicates that  $\delta^{18}\text{O}_{\text{Ca}}$  began to deplete before deposition of the tephra, while the  $\delta^{13}\text{C}_{\text{Ca}}$  depletion occurred after the tephra was deposited. Thereafter,  $\delta^{13}\text{C}_{\text{Ca}}$  values increased more slowly than  $\delta^{18}\text{O}_{\text{Ca}}$  values.

## Discussion

### *Carbon isotopes*

Carbon isotopes of lacustrine carbonate ( $\delta^{13}\text{C}_{\text{Ca}}$ ) reflect the isotopic composition of dissolved inorganic carbon (DIC). DIC is in turn a reflection of the balance between sources in groundwater and precipitation, atmospheric exchange, and  $p\text{CO}_2$  derived from respiration of isotopically depleted organic matter within the lake and its water sources (Dean and Stuiver, 1993; Herczeg and Fairbanks, 1987; McKenzie, 1985; Oana and Deevey, 1960; Siegenthaler and Eicher, 1986). Changes in  $\delta^{13}\text{C}_{\text{Ca}}$  may reflect changes in rates of biological productivity, atmospheric  $\text{CO}_2$  exchange within the lake, stratification, hydrology, or some combination of all of these factors, which may be directly or indirectly related to climatic change. Jellybean  $\delta^{13}\text{C}_{\text{Ca}}$  values ( $-3\text{‰}$  to  $-7.5\text{‰}$ ) are typical of productive lakes. Groundwater generally has relatively depleted values between  $-10\text{‰}$  and  $-15\text{‰}$ , while exchange with atmospheric  $\text{CO}_2$  via mixing and photosynthesis leads to DIC  $^{13}\text{C}$ -enrichment. The relatively depleted carbon isotope values of Jellybean Lake DIC probably represent the signature of  $^{13}\text{C}$ -depleted groundwater that is subsequently modified by biological productivity and atmospheric exchange.

The decrease in  $\delta^{13}\text{C}_{\text{Ca}}$  values above the White River tephra suggests a shift in biological activity and watershed run-off. The tephra could have lowered lake pH and increased turbidity. These changes might have led to decreased photosynthesis, decreased carbonate production, and/or increased carbonate dissolution (Figs. 4 and 6) and explain why  $\delta^{13}\text{C}_{\text{Ca}}$  recovery is notably longer than  $\delta^{18}\text{O}_{\text{Ca}}$ . Increased clastic sedimentation during this interval suggests that vegetation around the watershed was diminished and more clastic sediment was mobilized during precipitation events and/or spring run-off. The carbon isotope response to the White River tephra illustrates the complications associated with a direct climatic interpretation of  $\delta^{13}\text{C}_{\text{Ca}}$  in Jellybean Lake. Therefore, we chose to use the oxygen isotope data for climatic interpretations.

### *Oxygen isotopes*

Our results from water samples collected from a range of hydrological settings across the region suggest that variations in the oxygen isotope composition of precipitation ( $\delta^{18}\text{O}_{\text{p}}$ ) are responsible for driving the observed changes in Jellybean Lake  $\delta^{18}\text{O}$  and of the calcite formed in that lake water ( $\delta^{18}\text{O}_{\text{Ca}}$ ). What then controls temporal variation in the

Figure 6. Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$  and  $\delta^{13}\text{C}_{\text{Ca}}$  plotted on a (a) depth scale (cm) and (b) calibrated age scale (cal yr B.P.). Black bars indicate depths of radiocarbon ages. The horizontal line at 64 cm depth is the stratigraphic position of the White River tephra (Clague et al., 1995).

$\delta^{18}\text{O}_{\text{p}}$  in the region? Holdsworth et al. (1992) explored the relationship between  $\delta^{18}\text{O}_{\text{p}}$  and temperature in the Northwest Pacific. They found that the Mt. Logan Summit ice core  $\delta^{18}\text{O}$  (5340 m a.s.l.) was not significantly correlated with instrumental temperature records or paleotemperatures inferred from dendrochronologies. The  $\delta^{18}\text{O}$  data from the Eclipse ice core on Mount Logan (3017 m a.s.l.) have a weak correlation with temperature, explaining only 10–15% of the variance (Wake et al., 2002).

The average relation for middle and high latitudes between  $\delta^{18}\text{O}_{\text{p}}$  and mean annual surface temperature is  $\sim 0.6\text{‰}$  per  $^{\circ}\text{C}$  (Dansgaard, 1964; Rozanski et al., 1992). Combining this factor with the fractionation coefficient for calcite formation and lake water temperature,  $-0.25\text{‰}$  per  $^{\circ}\text{C}$  (Friedman and O’Niel, 1977), leads to an estimated change in  $\delta^{18}\text{O}_{\text{Ca}}$  of  $\sim 0.35\text{‰}$  per  $^{\circ}\text{C}$  of atmospheric temperature change for Jellybean Lake (e.g., Anderson et al., 2001; Yu et al., 1997). The observed range of  $\delta^{18}\text{O}_{\text{Ca}}$  in Jellybean Lake is  $\sim 2.0\text{‰}$  (Fig. 6), corresponding to a

temperature range of  $\sim 5.7^{\circ}\text{C}$  which we consider to be too large for this period based on comparison with other regional paleorecords (Heusser et al., 1985; Hu et al., 2001). In addition, the abrupt  $\delta^{18}\text{O}_{\text{Ca}}$  shifts during the last 1500 yr are up to  $1.5\text{‰}$ , which would correspond to a change of  $\sim 4.3^{\circ}\text{C}$ . These large inferred temperature changes, combined with the poor correlation between Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$  and a 300-yr dendrochronology record from the Mackenzie River delta, interpreted to reflect growing season temperatures for the region (Szeicz and MacDonald, 1995, 1996), suggest that temperature is not the primary control. Furthermore, isotope-modeling studies by Bowen and Wilkinson (2002) identify northwestern Canada as an area where  $\delta^{18}\text{O}_{\text{p}}$  has high magnitude deviations from typical temperature controlled relationships. Based on these observations, we conclude that multi-annual  $\delta^{18}\text{O}_{\text{p}}$  variation in this region is not driven by temperature changes alone. We suggest that temporal changes in atmospheric circulation across the St. Elias Mountains are the major control on the

oxygen isotope composition of precipitation in the interior of the southern Yukon and hence hydrologically open lakes such as Jellybean.

#### Oxygen isotopes, precipitation, and atmospheric circulation

Numerous oxygen isotope studies of sediment from evaporation-insensitive lakes have inferred past changes in atmospheric circulation (e.g., Edwards et al., 1996; Hammerlund et al., 2002; Jones et al., 2004; Rosqvist et al., 2004; Wolfe et al., 2003; Yu et al., 1997). Precipitation data show that maritime air masses reaching the coast of southwest Alaska are relatively  $^{18}\text{O}$ -enriched (Adak,  $-8\%$  to  $-11\%$ ) compared to precipitation falling from these same air masses in the interior of the Yukon (Whitehorse,  $-18\%$  to  $-21\%$ ; IAEA/WMO, 2001). Such large depletions occur because of the effects of Rayleigh distillation during air mass uplift, rainout, and transport across the average  $\sim 3000\text{-m}$ -high topographic barrier of the St. Elias Mountains (Rozanski et al., 1993). We hypothesize that changes in air mass trajectory and the intensity of moisture transport through time across the St. Elias Mountains control the mean annual isotopic value of precipitation falling in the interior of the Yukon. A likely mechanism is multi-decadal fluctuations in the location and strength of the AL that directs maritime air masses into the interior with varying effects on fractionation during transport.

The NP index (NPI) represents changes in AL position and strength (Trenbith and Hurrell, 1994). Figure 7 shows the normalized Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$ -record for the last 100 yr compared with the NP index. Although the NPI is calculated for each year, the Jellybean data are integrations of 3–6 yr during the 20th century that are not regularly spaced in time. We used the 5-yr running average of the NPI to identify anomaly values for the 23 yr that corresponded with the  $^{210}\text{Pb}$ -determined ages for the sediment samples.

Correlation of the 23 pairs of data is significant at the 0.05 confidence level ( $r = 0.48$ ) and accounts for a relatively small fraction of explained variance ( $r^2 = 0.23$ ). However, a relatively low correlation might be expected given the uncertainties in our age model and the nature of the signals being recorded. The NPI is a seasonal signal because the AL is strongest in the winter and diminishes during the summer. The Jellybean Lake- $\delta^{18}\text{O}_{\text{Ca}}$  data represent an integration over 3- to 6-yr periods and reflects groundwater- $\delta^{18}\text{O}$  which tends to smooth the effects of seasonal variations. It may be that this multi-annual  $\delta^{18}\text{O}_{\text{p}}$  signal is predominantly influenced by variability in fall and winter precipitation. A similar effect has been observed for inter-annual ice accumulation on Mt. Logan where only winters of high accumulation were found to have a strong connection with atmospheric circulation (Rupper et al., 2004). If this assessment is correct and the limitations of the isotope time series are kept in mind, then the correlation can be seen as supporting a relationship between Jellybean Lake- $\delta^{18}\text{O}_{\text{Ca}}$  and AL intensity/position.

Observations between 1976 and 1988 A.D. show the AL was more intense and shifted eastward, advecting warm moist air along the northwest Pacific coast from the south-southeast, leading to increased coastal precipitation (Cayan and Peterson, 1989; Mantua et al., 1997; Trenbith and Hurrell, 1994). During this period Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$  values were relatively depleted. We propose that when the AL is eastward and/or stronger, the effects of Raleigh distillation are enhanced and precipitation reaching the interior is more depleted. An eastward and/or intensified AL (negative NPI anomaly) delivers strong southerly winds directly into the mountain barrier trending northwest to southeast along the Alaskan coast. It is possible that such an orientation in moisture flow, directly into the large mountains, would enhance rainout on the coastal side. Consequently, more fractionated vapor is vigorously forced

Figure 7. Normalized Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$  data (black line) are shown with the NP index since 1900 A.D. (gray shade is annual data, dashed line is 5 yr running average; Trenbith and Hurrell, 1994). Negative NPI anomalies represent a strong/eastward Aleutian Low. Error bars on  $\delta^{18}\text{O}_{\text{Ca}}$  data represent  $\pm 5\text{-yr}$  age uncertainty based on the  $^{210}\text{Pb}$  and  $^{137}\text{Cs}$  measurements (Fig. 3).

up and over the barrier into the interior. Stronger leeward winds and an enhanced rain shadow effect would lead to further fractionation of the reduced amount of precipitation reaching the interior Yukon (Table 4).

In contrast, when the AL is westward and/or weaker, fractionation is decreased during transport and  $\delta^{18}\text{O}_p$  is relatively  $^{18}\text{O}$ -enriched. Historically, positive NPI anomalies represented a weaker and/or westward position of the AL. This causes less vigorous meridional moisture transport from the south-southeast along the northwest Pacific coast and allows more moisture flow from the Bearing Sea, to the west, into interior Alaska. During positive NPI anomalies, Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$  is relatively enriched, reflecting decreased fractionation of precipitation during transport. A more zonal flow pattern and westerly moisture trajectory is able to move more parallel to the coastal mountain barrier and may avoid the same degree of uplift, cooling, and rainout than when moisture flow is more directly into the mountain barrier. In this case, less fractionated moisture would be more likely to infiltrate the northeast–southwest trending valleys leading into the interior of the Yukon (Streten, 1974). We infer that the primary control on  $\delta^{18}\text{O}_p$  in the southwest Yukon is temporally changing moisture trajectories into and over the coastal mountains driven by the strength and the position of the AL. Assuming this is correct, the  $\delta^{18}\text{O}_{\text{Ca}}$  from Jellybean Lake provides a record of Holocene changes in intensity and/or position of the AL (Fig. 8).

### Holocene paleoclimate

The Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$  record provides Holocene paleoclimatic information at higher temporal resolution than available from previous work (Fig. 8). While the comparison of sediment core to instrumental climate data suggests a relationship between lake  $\delta^{18}\text{O}_{\text{Ca}}$  and characteristics of the AL, such as defined by the NPI, it is important to recognize that data from regional networks of sites are necessary to unambiguously distinguish between changes in AL strength and position over time. Keeping this limitation in mind in interpreting the isotopic record, the data suggest that AL

position and strength during the early to middle Holocene, 7500–4500 cal yr B.P., was generally weaker than and/or westward from today's location. Between ~4500 and 3500 cal yr B.P., circulation intensified and was similar to today, with airflow predominantly from the southwest (Wahl et al., 1987). After ~3500 cal yr B.P. a steady trend towards enriched  $\delta^{18}\text{O}_{\text{Ca}}$  reflects a westward and/or weaker AL. By ~2000 cal yr B.P. the AL position was on average farther west and/or weaker than any time during the last ~7500 yr. Other paleoclimatic studies report greater effective moisture in the central and southern Yukon prior to ~2000 cal yr B.P. (Pienitz et al., 2000). These observations are consistent with the isotope results from Jellybean Lake. Previous studies of regional synoptic climatology suggest that a weaker/westward positioned AL is related to increased moisture delivery to interior regions (Edwards et al., 2001).

Our record also suggests that abrupt changes in AL position/strength were more frequent during the last ~2000 yr than the preceding period. The decreases in  $\delta^{18}\text{O}_{\text{Ca}}$  ~1200 cal yr B.P. represent rapid eastward shifts and/or intensification of the AL. Between ~500 and 300 cal yr B.P.,  $\delta^{18}\text{O}_{\text{Ca}}$  became relatively enriched again, reflecting a westward shift and/or weakening. Another easterly shift and/or intensification ~1700 A.D. correspond with cooler spring and summer south coastal land temperatures (Wiles et al., 1998). AL variability since 1900 A.D. indicates a weak/westward period in the early part of the century that corresponds with the termination of south coastal glacial advances and the end of the Little Ice Age (Wiles et al., 1999).

The oxygen isotope evidence presented here suggests high frequency changes in AL location/strength have occurred throughout the Holocene. However, the largest secular changes occurred after ~3500 cal yr B.P. Large changes in AL intensity and position have been shown to be accompanied by changes in ocean circulation and sea surface temperatures that would likely effect marine ecosystems (Mantua et al., 1997). Salmon catch records during the 20th century suggest a correlation between the eastward shifted and strong AL between 1976 to 1988 A.D. and increased production of Alaskan salmon (Hare and Francis, 1994; Mann et al., 1998). A reconstruction of Alaskan sockeye salmon abundance indicates a prominent multi-century change from lower to higher average abundance ~1200 cal yr B.P. (Finney et al., 2002; Fig. 8). This increase corresponds with an eastward and/or intensified AL indicated by Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$ . Similarly, a multi-decade decline in salmon abundance in the early 19th century (Finney et al., 2000) coincides with a westward and/or weaker AL. The record from Jellybean Lake reflecting changes in AL position/strength is consistent in terms of the timing and direction with late Holocene changes in Alaskan salmon abundance.

Neoglaciation was initiated in the St. Elias and Coast Mountains ~3400 cal yr B.P. (Calkin et al., 2001; Denton and Karlen, 1977; Fig. 8) and broadly corresponds with a

Table 4  
Relationships between Aleutian Low,  $\delta^{18}\text{O}$ , Gulf of Alaska, and Alaskan salmon

Aleutian Low intensity (NP Index <sup>a</sup> )	Strong (–)	Weak (+)
Oxygen isotope fractionation during transport to southern interior Yukon	More	Less
SW-interior Yukon $\delta^{18}\text{O}_p$	$^{18}\text{O}$ -depleted	$^{18}\text{O}$ -enriched
Jellybean Lake $\delta^{18}\text{O}_{\text{Ca}}$	$^{18}\text{O}$ -depleted	$^{18}\text{O}$ -enriched
Gulf of Alaska boundary currents	Strong	Weak
Gulf of Alaska SSTs	Warm	Cold
Alaskan salmon abundance <sup>b</sup>	Higher	Lower
Karluk Lake $\delta^{15}\text{N}^c$	$^{15}\text{N}$ -enriched	$^{15}\text{N}$ -depleted

<sup>a</sup> Trenbith and Hurrell (1994).

<sup>b</sup> Mantua et al. (1997).

<sup>c</sup> Finney et al. (2002).

Figure 8. Normalized Jellybean Lake  $\delta^{18}\text{O}_{\text{Ca}}$  is shown with sedimentary- $\delta^{15}\text{N}$  from Karluk Lake, Alaska, since 2200 cal yr B.P. (Finney et al., 2002).  $\delta^{15}\text{N}$  is a proxy for sockeye salmon abundance where enriched  $\delta^{15}\text{N}$  records periods of higher salmon abundance (Finney et al., 2000). Note that changes during the 20th century also reflect the influence of commercial fishing in addition to that of climate. Timing of glacier advances in the St. Elias Mountains is indicated by vertical bars (Denton and Karlen, 1977). Vertical line on  $\delta^{18}\text{O}_{\text{Ca}}$  scale labeled 'modern' is an average of the last 30 yr of data. WRA indicates the stratigraphic position of the White River tephra.

period when the AL was eastward and/or stronger before a shift westwards and/or weakening after  $\sim 3000$  cal yr B.P. The onset of Neoglaciation may also be attributed to decreasing solar insolation in addition to changes in the seasonality of precipitation. Increased moisture delivery during winter by an intensified/eastward AL could lead to coastal glacier advances (e.g., Heusser et al., 1985). Our results are consistent with other studies that suggest neoglacial climate corresponds with secular shifts to an intensified/eastward AL and increasing moisture delivery to coastal glaciers and the St. Elias and Coast Mountains (e.g., Heusser et al., 1985).

The oxygen isotope data indicate that changes in the intensity of the AL during the early and middle Holocene differed from the late Holocene. Dyke and Saville (2000) noted a similar circulation change over in the western Arctic Ocean. During the middle and early Holocene, the Beaufort Gyre was positioned either farther west than it is today or had intensified. After  $\sim 2000$  cal yr B.P., it weakened and contracted or moved. The effect was reduced summer sea-ice extent that may have enticed the eastward migration of bowhead whales and possibly the Thule culture (Dyke and Saville, 2000, 2001). Around  $\sim 1200$  cal yr B.P. a trend toward an intensified/eastward AL began

and subsequent AL variability was rapid and more frequent. When the Beaufort Gyre and associated anticyclonic atmospheric circulation around the polar vortex weakened and contracted, the AL strengthened. The oxygen isotope record presented here is consistent with other regional records of natural climate variability, connecting two prominent high-latitude atmospheric and oceanic circulation features in the western Canadian Arctic and North Pacific region.

## Acknowledgments

We thank Mary E. Edwards, Mathias Viulle, and Carsten Braun for helpful discussions during the preparation of this paper. We also thank Britt Haugen, Dan Nelson, Joe Rodgers, and Nathan Stansell for their kind assistance in the field. Finally we thank Eric Steig, Summer Rupper, and an anonymous reviewer for constructive comments that improved the paper. The National Science Foundation (ATM-0296157 and ATM-0097127) and the Department of Geosciences of the University of Massachusetts Amherst supported this work.
